How trapped surfaces jump in 2+1 dimensions

Abstract

When a lump of matter falls into a black hole it is expected that a marginally trapped tube when hit moves outwards everywhere, even in regions not yet in causal contact with the infalling matter. But to describe this phenomenon analytically in 3+1 dimensions is difficult since gravitational radiation is emitted. By considering a particle falling into a toy model of a black hole in 2+1 dimensions an exact description of this non-local behaviour of a marginally trapped tube is found.

1 Introduction

A black hole is defined by its event horizon; a boundary in spacetime, such that no event inside it can ever be seen from the outside. With this definition it is impossible to locate the event horizon without knowledge about the infinite future. Attempts to make alternative definitions of a black hole involve trapped surfaces that occur in the interior [1, 2, 3]. A trapped surface is a closed, spacelike surface such that both families of light rays orthogonal to it converge. The terminology of concepts closely related to these trapped surfaces might need to be made clear: A surface such that only one of the orthogonal families of light rays converges while the other has zero convergence is referred to as a marginally trapped surface. If a surface is embedded in a hypersurface on which an outer direction is defined in a manner that would be intuitive in an asymptotically simple spacetime, and this surface is such that the outgoing family of light rays orthogonal to it converges, it is called outer trapped, regardless of the behaviour of the ingoing family of light rays. Marginally outer trapped surfaces are defined in a similar manner. All of these surfaces are quasilocal properties of spacetime – unlike the globally defined event horizon – since the definitions only involve the surfaces themselves and their infinitesimal surroundings. For this reason trapped surfaces are of importance to numerical relativists, since the occurence of such is the only practical way to identify a black hole in a simulated evolution of spacelike hypersurfaces. In such simulations the trapped surfaces sometimes make discontinuous "jumps" outwards [4, 5]. This phenomenon is expected when matter is falling into the black hole [6].

A marginally trapped tube is a hypersurface foliated by marginally trapped surfaces. The marginally trapped tubes we will come across will be null and satisfy some other constraints that qualify them as isolated horizons [7]. It is desirable to find an exact description of how a marginally trapped tube is affected when hit by matter. This has been done in the case of a spherically symmetric shell of dust falling into a black hole [8]. However, if a localized "lump" of matter is falling into a black hole it is much more difficult to find an analytical description since gravitational radiation will be emitted. But it is expected that the jump in this case will be in some sense non-local; that the jump will take place also in regions not yet in causal contact with the infalling matter. This is a consequence of the quasilocal property of a trapped surface; light rays emitted from a region on a surface may converge, but whether the whole surface is closed or not depends on circumstances elsewhere. Because of the difficulties in 3+1 dimensions we instead tackle the problem in 2+1 dimensions where there is no gravitational radiation. We consider a toy model of a black hole and let a particle fall into it in order to find an exact description of how the marginally trapped tube jumps outwards in this non-local way.

2 The black hole and trapped surfaces

The existence of a black hole in a 2+1-dimensional spacetime with constant negative curvature was first discovered by Bañados *et al* [9]. This is called a BTZ black hole. It is obtained by identifying points in anti-de Sitter space using an isometry [10].

2+1-dimensional anti-de Sitter space can be defined as the hypersurface

$$X^2 + Y^2 - U^2 - V^2 = -1, \tag{1}$$

embedded in a four dimensional spacetime with metric

$$ds^2 = dX^2 + dY^2 - dU^2 - dV^2. \tag{2}$$

It has constant curvature which is negative. Each point can be represented by a matrix

$$\boldsymbol{g} = \begin{pmatrix} U+Y & X+V \\ X-V & U-Y \end{pmatrix}, \tag{3}$$

so that

$$\det \boldsymbol{g} = -X^2 - Y^2 + U^2 + V^2 = 1. \tag{4}$$

But this is a group element of $SL(2,\mathbb{R})$, consisting of all two by two matrices with real matrix elements and determinant one. Furthermore, any isometry can be described by letting the group act on itself. Isometries leaving the unit element fixed can be written

$$\boldsymbol{g} \to \boldsymbol{g}' = \boldsymbol{g}_1 \boldsymbol{g} \boldsymbol{g}_1^{-1}, \tag{5}$$

where $\boldsymbol{g}_1 \in SL(2,\mathbb{R})$. Transformations of the type (5) will have a line of fixed points and the nature of this line is determined by the trace of $\boldsymbol{g}_1$. If $\mathrm{Tr}\boldsymbol{g}_1 < 2$ it will be timelike, if $\mathrm{Tr}\boldsymbol{g}_1 = 2$ it will be lightlike and if $\mathrm{Tr}\boldsymbol{g}_1 > 2$ it will be spacelike.

The embedding coordinates are convenient to use in calculations, but for visualization the intrinsic coordinates (t, ρ, ϕ) [11] are a better choice. They are given by

$$\begin{aligned} X &= \frac{2\rho}{1-\rho^2}\cos\phi & & \\ Y &= \frac{2\rho}{1-\rho^2}\sin\phi & & 0 \leq \rho < 1 \\ U &= \frac{1+\rho^2}{1-\rho^2}\cos t & & 0 \leq \phi < 2\pi \\ V &= \frac{1+\rho^2}{1-\rho^2}\sin t & & -\pi \leq t < \pi. \end{aligned} \tag{6}$$

The metric in these coordinates is

$$ds^2 = -\left(\frac{1+\rho^2}{1-\rho^2}\right)^2 dt^2 + \frac{4}{(1-\rho^2)^2}(d\rho^2 + \rho^2 d\phi^2). \tag{7}$$

With this choice of coordinates anti-de Sitter space is depicted as a cylinder. The timelike coordinate t runs along the cylinder, and the spatial slices of constant t are Poincaré disks. On the disk, ρ and ϕ are the radial and angular coordinates respectively and $\mathscr{J}$ is situated at the boundary $\rho = 1$.

To create a black hole we choose a group element

$$\boldsymbol{g}_{BH} = \begin{pmatrix} \cosh\mu & \sinh\mu \\ \sinh\mu & \cosh\mu \end{pmatrix}, \tag{8}$$

where μ is an arbitrary real constant. Then we act with it on anti-de Sitter space through conjugation as in Eq. (5), and identify points that are transformed into each other. The region between the two identified surfaces $Y = V\tanh\mu$ and $Y = -V\tanh\mu$ can be taken to represent the quotient space. The result is that a spacelike slice in there has the topology of a cylinder. It has constant negative curvature still and is free from singularities, unless it contains any fixed points which are located at the spacelike line $Y = V = 0$. Starting from the slice $t = -\pi/2$ it is seen that the cylinders shrink in the periodical direction as t increases, until one dimension suddenly disappears at $t = 0$, and all that is left is the line of fixed points. A geodesic ending at this singular line ends after only a finite parameter time, meaning that this spacetime is geodesically incomplete. The event horizon is the backward light cone of the last point on $\mathscr{J}$, i.e. the point where the singular line meets $\mathscr{J}$. In the embedding coordinates the event horizons are given as the quotient of the two surfaces $X = \pm U$. Note that there are two asymptotic regions, just like in the Schwarzschild black hole. A picture of this model of a black hole can be seen in Fig. 1.

The black hole spacetime is locally anti-de Sitter everywhere except at the singular line. On a spacelike surface, the only way to distinguish it from anti-de Sitter space is through the holonomy of the black hole: If a vector is parallel transported along a curve closed by the identification it will also be transformed by the group element effecting the identification.

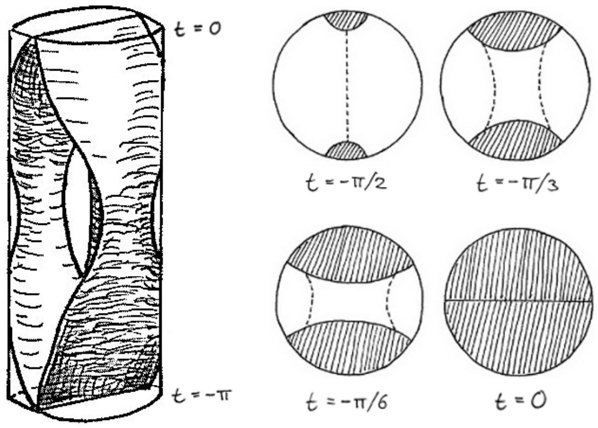

Figure 1: The BTZ black hole. The cylinder is depicting 2+1-dimensional anti-de Sitter space in which the identification surfaces are drawn. To the right are spatial slices with different values of constant t. The shaded regions are cut away by the identification, but only the top left disk where $t = -\pi/2$ will turn into a smooth surface by the identification. On the bottom right disk where $t = 0$ nothing is left but the singularity. The dashed lines on the disks are the event horizons. (This figure is a paraphrase on a figure originally drawn by Sören Holst [12].)

Finding trapped surfaces – or rather trapped curves, since we are in 2+1 dimensions – is easy. Consider the intersection of two light cones with vertices at the singularity. Light rays emanating orthogonally from such curves obviously converge. Moreover they coincide with flow lines of the identifying isometry and are therefore closed to smooth curves by the identification. Hence they are trapped. It is easily seen that the event horizon is a marginally trapped tube, a surface foliated by marginally trapped curves. Since trapped surfaces can not exist outside the event horizon according to the cosmic censorship hypothesis, the marginally trapped tube – that is the event horizon in this model – is also the boundary of the region containing trapped curves.

In fact this is the complete picture: all marginally trapped curves lie on the event horizon. To see this, consider Raychaudhuri's equation [13] for the expansion θ of a congruence of lightlike geodesics in 2+1 dimensions. With k^a being the tangent vector of a given geodesic we have

$$\dot{\theta} = -\theta^2 - R_{ab}k^a k^b. \tag{9}$$

If we impose Einstein's vacuum equation $R_{ab} = \lambda g_{ab}$ the second term vanishes since $k^2 = 0$ for a lightlike geodesic. We are left with

$$\dot{\theta} = -\theta^2, \tag{10}$$

which shows that a congruence of lightlike geodesics that have zero convergence at some point, must continue to have zero convergence. The conclusion is that a marginally trapped curve must lie on a null plane[1]. It is not difficult to show that only the null plane containing a fixed point on $\mathscr{J}$ contains smooth and spacelike closed curves.

---

[1] This does not hold in 3+1 dimensions, since Raychaudhuri's equation will then contain extra terms.

As a side note, there is a theorem that says that a region of a spacelike hypersurface bounded by an outer trapped surface in one direction and by an outer untrapped surface in the other must contain a marginally outer trapped surface [14]. In this model the statement is almost obvious. Any smooth spacelike surface passing through the interior of the black hole will contain a smooth closed curve lying on the event horizon and thus being a marginally outer trapped curve. Since it lies on the event horizon it also separates the region containing trapped curves from the region not containing trapped curves on the surface.

3 The infalling particle

Just like a black hole was obtained by identifying points, a point particle can be modelled using the same trick. Note that the matrix of Eq. (8) has a trace larger than two, and therefore has a spacelike line of fixed point. If we instead choose the group element

$$\boldsymbol{g}_P = \begin{pmatrix} 1 & 2a \\ 0 & 1 \end{pmatrix}, \tag{11}$$

with a being an arbitrary real constant, and identify points in anti-de Sitter space through conjugation, the line of fixed points will be lightlike since $\mathrm{Tr}\boldsymbol{g}_P = 2$. A fundamental region containing one representative of every point in the quotient space can be chosen by cutting away the region between the two identified surfaces $Y = \pm a(X - V)$. The effect is that a surface of constant t now has the topology of a cone, with the tip of the cone being a fixed point of the identification. This setup perfectly well describes a point particle [15, 16]. The particle is situated at the conical singularity, and it is a lightlike particle since its world line is lightlike. Considering a sequence of Poincaré disks it is seen that the particle comes in from infinity at $t = -\pi/2$, then it traverses the disk until it finally leaves at $t = \pi/2$. On the disk space is locally anti-de Sitter everywhere except at the singularity, and the only way to notice the presence of the particle is to travel around it and reveal its holonomy.

We are now ready to set up a model where we let the particle fall into the black hole. This is done by combining the holonomy $\boldsymbol{g}_P$ of the particle and the holonomy $\boldsymbol{g}_{BH}$ of the black hole to a total holonomy $\boldsymbol{g}_{tot} = \boldsymbol{g}_P\boldsymbol{g}_{BH}$. If the constants a and μ are chosen so that $|\mathrm{Tr}\boldsymbol{g}_{tot}| > 2$, the transformation $\boldsymbol{g} \to \boldsymbol{g}_{tot}\boldsymbol{g}\boldsymbol{g}_{tot}^{-1}$ will have a spacelike line of fixed points. The easiest way to see what has now happened is by using a graphical approach as in Fig. 2. As the particle approaches the center of the disk it is seen how the identification surfaces of the particle eventually begin to intersect the identification surfaces of the black hole. These points of intersection are fixed points under the combined transformation $\boldsymbol{g}_{tot}$. The infalling particle has thus caused the singularity of the black hole to find a new location, which in turn affects the location of the event horizon. Note that before the particle crosses it, the event horizon will now have a kink. This kink nicely illustrates the teleological nature of the event horizon; it has acquired a kink not because of something

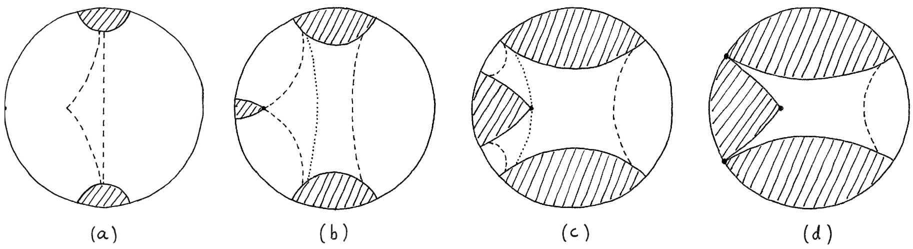

Figure 2: A sequence of Poincaré disks shows what happens when the particle falls into the black hole (compare with Fig. 3). (*a*) The particle comes in from infinity. At this point the event horizon has a kink and does not contain any marginally trapped curves. (*b*) The particle meets the event horizon which from here on will be a smooth marginally trapped tube. (*c*) The isolated horizon that would have been the event horizon had the particle not been there is hit by the particle. From this point on it ceases to be a smooth marginally trapped tube. (*d*) A fixed point appears on $\mathscr{J}$ as the identification surfaces of the particle and the black hole begin to intersect. The dashed line to the right is not relevant in these figures; it is just an artefact of the other asymptotic region.

that has happened to it in the past, but because of something that will happen to it in the future.

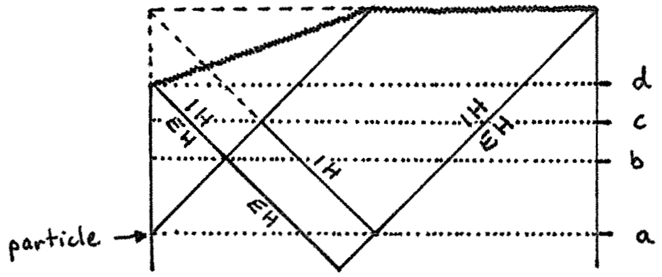

Figure 3: A Penrose diagram of our model clearly illustrates how the isolated horizon "jumps" outwards when it is hit by the particle. The dashed lines show the location of the singularity and the event horizon had the particle not been there.

That the event horizon is not everywhere smooth means that it is not completely foliated by marginally trapped curves. We know that marginally trapped curves are found on null planes and that a null plane is smooth only if it contains a fixed point on $\mathscr{J}$. It is a crucial fact that the light cone on which the path of the particle lies splits the spacetime into two qualitatively different parts. In the outer region the holonomy is $\boldsymbol{g}_{tot}$ and the marginally trapped curves lie on the event horizon. In the inner region – where the event horizon has a kink – the holonomy is $\boldsymbol{g}_{BH}$ and it is therefore impossible to distinguish from the BTZ spacetime. The smooth null plane containing marginally trapped curves is thus what would have been the event horizon had the particle not been there. It is an isolated horizon in the terminology of ref. [7]. After it has been hit by the particle – in the outer region – this surface is no longer smooth.

The marginally trapped tube thus consists of two parts. When the particle hits it in the interior of the black hole, the isolated horizon is seemingly destroyed but then reappears on the event horizon, it “jumps”. This is clearly illustrated in the conformal diagram of Fig. 3. We have thus found a reasonable and exact illustration of how marginally trapped curves jump when hit by matter.

4 Conclusions

By considering a toy model of a black hole in 2+1 dimensions and letting a point particle fall into the black hole, we have seen how the marginally trapped tube splits into two parts. This exact description of the splitting illustrates the non-local jump described in the introduction. As a concluding remark it is worth noting that since the world line of the particle is singular, the two parts of the marginally trapped tube can not be connected. To get around this problem one could consider a small tube of null dust instead of a point particle. It might be interesting to see what the marginally trapped tube would look like in this more complicated model; in particular if it would be smooth, and if so, if the smooth part joining the two isolated horizons would be timelike or spacelike.

Acknowledgements

I would like to thank Ingemar Bengtsson for bringing my attention to the problem and for his significant support. I would also like to thank Sören Holst for accepting the similarities between Fig. 1 and his original.
